Barrier Option Pricing

Degree Project in Mathematics, First Level

Niklas Westermark

Abstract

This thesis examines the performance of five option pricing models with respect to the pricing of barrier options. The models include the Black-Scholes model and four stochastic volatility models ranging from the single-factor stochastic volatility model first proposed by Heston (1993) to a multi-factor stochastic volatility model with jumps in the spot price process. The stochastic volatility models are calibrated using four different loss functions to examine the loss functions effect on the resulting barrier option prices. Our results show that the Black-Scholes model yields significantly different prices than the stochastic volatility models for barriers far from the current spot price. The prices of the four stochastic volatility models are however very similar. We also show that the choice of loss function for parameter estimation has little effect on the obtained barrier option prices.

Table of contents

1.   Introduction

Ever since the presentation of the famous Black & Scholes model [7], academics and practitioners have made numerous attempts to relax the restrictive assumptions that make the model inconsistent with observed prices in the market. Particular interest has been directed towards the assumption of constant volatility, which makes the model unable to generate non-normal return distributions and the well-known volatility smile, consistent with empirical findings on asset returns [12].

Examples of extensions of the Black-Scholes model include models that allow for stochastic volatility and jumps in the underlying return process. Many different models have been proposed, ranging from single-factor stochastic volatility models, to multi-factor models with log-normally distributed jumps in the stock price process as well as stochastic interest rates (see e.g. [3], [4], [5], [11], [19] and [27]).

In a recognized paper, Schoutens, Simons & Tistaert [23] show that although there are many option pricing models available that very accurately can explain observed prices of plain vanilla options, the models may produce inconsistent prices when applied to more exotic derivatives. In this thesis, we extend the results of [23] by conducting a similar analysis with four stochastic volatility models, including two multi-factor stochastic volatility models not examined in [23]. All four models allow for non-normal return distributions and non-constant volatility and have proven to be effective in the pricing of plain vanilla call and put options (see e.g. [3], [5] and [23]). We also extend the estimation technique by calibrating the models using four different loss functions, and examine how the choice of loss function potentially affects the pricing performance of the models.

To estimate the model parameters, we use the same data set as in [23], i.e. the implied volatility surface of the Eurostoxx 50 index on the 7th of October 2003. Using the estimated model parameters, we analyze the models' pricing performance with respect to the commonly traded exotic options called *barrier options*, and compare the obtained prices using the different models and loss functions.

Our results show that the prices of barrier options differ significantly between the Black-Scholes model and the stochastic volatility models. We also show that the choice of loss function for estimation of model parameters in the stochastic volatility models have little effect on the resulting barrier option prices.

1.1. Barrier options

A barrier option is a path-dependent option whose pay-off at maturity depends on whether or not the underlying spot price has touched some pre-defined barrier during the life of the option. In this thesis, we will limit our attention to four of the most common barrier options, namely up-and-in (UI), up-and-out (UO), down-and-in (DI) and down-and-out (DO) call options.

To describe the pay-off structures of the barrier options, define the maximum and the minimum of the spot price process $S = \{S_t, 0 < t < T\}$ as $m_S = \inf\{S_t; 0 < t < T\}$ and $M_S = \sup\{S_t; 0 < t < T\}$.

The UI call option is worthless unless the underlying spot price S hits a pre-determined barrier $H > S_0$ during the life of the option, in which case it becomes a standard call option. Hence, its pay-off at maturity is:

$$\Phi_{UI}(S_T, M_S) = (S_T - K)^+ \mathbf{1}(M_S \geq H) \tag{1.1}$$

where $\mathbf{1}(M_S \geq H)$ is an indicator function equal to one if $M_S \geq H$ and zero otherwise.

For the UO call option, the relationship is reversed: the UO call option is a standard call option unless the underlying spot price hits the barrier, in which case it becomes worthless:

$$\Phi_{UO}(S_T, m_S) = (S_T - K)^+ \mathbf{1}(m_S < H) \tag{1.2}$$

For DI and DO call options, the barrier H is set below the spot price at inception, $H < S_0$. The pay-off structures of the DI and DO options follow analogously: the DI call option is worthless unless the barrier H is reached some time during the life of the trade, in which case it becomes a plain vanilla call option. The DO option, on the other hand, is a standard call option unless the spot price reaches the lower barrier during the life of the option, in which case it becomes worthless. The pay-off structures of the DI and DO call options are:

$$\Phi_{DI}(S_T, m_S) = (S_T - K)^+ \mathbf{1}(m_S \leq H) \tag{1.3}$$

$$\Phi_{DO}(S_T, M_S) = (S_T - K)^+ \mathbf{1}(M_S > H) \tag{1.4}$$

2. Model presentation

We will assume that the reader has a basic knowledge of the basic Black-Scholes framework and will thus refrain from describing the Black-Scholes model in detail. The interested reader is referred to [21] for an economic outline and to [6] for a description of the mathematical framework.

For all models, we consider the risk-neutral dynamics of the stock price. We let $S = \{S_t, 0 \leq t \leq T\}$ denote the stock price process and $\varphi_T(\cdot)$ denote the characteristic function of the natural logarithm of the terminal stock price $s_T = \log(S_T)$, where $\log(\cdot)$ denotes the natural logarithm function. The constants r and δ will denote the, both constant and continuously compounded, interest rate and dividend yield, respectively. Further, we let $W_t^{\mathbb{Q}}$ denote a $\mathbb{Q}$-Wiener process.

2.1. Stochastic volatility model (SV)

Many different stochastic volatility models have been proposed, but we will limit our attention to the Heston [19] stochastic volatility model, henceforth denoted SV, in which the spot price is described by the following stochastic differential equations (SDEs) under $\mathbb{Q}$:

$$\frac{dS_t}{S_t} = (r - \delta)dt + \sqrt{V_t}dW_t^{\mathbb{Q}\,(1)} \tag{2.1}$$

$$dV_t = \kappa(\theta - V_t)dt + \sigma\sqrt{V_t}dW_t^{\mathbb{Q}\,(2)} \tag{2.2}$$

$$dW_t^{\mathbb{Q}\,(1)}dW_t^{\mathbb{Q}\,(2)} = \rho dt \tag{2.3}$$

where V_t is the stochastic variance and the parameters κ, θ, σ and ρ represent the speed of mean reversion, the long-run mean of the variance, the volatility of the variance process and the correlation between the variance and stock price processes, respectively. In addition to these parameters, the model requires the estimation of the instantaneous spot variance V_0.

Using the same representation of the parameters as in equations (2.1) – (2.3), the characteristic function of s_T takes the following form:

$$\varphi_T^{SV}(u) = S_0^{iu} f(V_0, u, T) \tag{2.4}$$

where

$$f(V_0, u, T) = \exp\{A(u, T) + B(u, T)V_0\} \tag{2.5}$$

$$A(u, T) = (r - \delta)iuT + \frac{\kappa\theta}{\sigma^2}\left[(\kappa - \rho\sigma iu - d)T - 2\log\left(\frac{1 - ge^{-dT}}{1 - g}\right)\right] \tag{2.6}$$

$$B(u, T) = \frac{\kappa - \rho\sigma iu - d}{\sigma^2}\left[\frac{1 - e^{-dT}}{1 - ge^{-dT}}\right] \tag{2.7}$$

$$d = \sqrt{(\rho\sigma iu - \kappa)^2 + \sigma^2(iu + u^2)} \tag{2.8}$$

$$g = (\kappa - \rho\sigma iu - d)/(\kappa - \rho\sigma iu + d) \tag{2.9}$$

2.2. Stochastic volatility model with jumps (SVJ)

We extend the SV model in the previous section along the lines of [4], by adding log-normally distributed jumps to the stock price process. In this model, here denoted SVJ, the return process of the spot price is described by the following set of SDEs under $\mathbb{Q}$:

$$\frac{dS_t}{S_t} = (r - \delta - \lambda\mu_J)dt + \sqrt{V_t}dW_t^{\mathbb{Q}\,(1)} + J_t dY_t \tag{2.10}$$

$$dV_t = \kappa(\theta - V_t)dt + \sigma\sqrt{V_t}dW_t^{\mathbb{Q}\,(2)} \tag{2.11}$$

$$dW_t^{\mathbb{Q}\,(1)}dW_t^{\mathbb{Q}\,(2)} = \rho dt \tag{2.12}$$

where $Y = \{Y_t, 0 \leq t \leq T\}$ is a Poisson process with intensity $\lambda > 0$ and J_t is the jump size conditional on a jump occurring. All other parameters are defined as in (2.1) – (2.3). The subtraction of $\lambda\mu_J$ in the drift term compensates for the expected drift added by the jump

component, so that the total drift of the process, as required for risk-neutral valuation, remains $(r - q)dt$.

As mentioned, the jump size is assumed to be log-normally distributed:

$$\log (1 + J_t) \sim N \left(\log (1 + \mu_J) - \frac{\sigma_J^2}{2}, \sigma_J^2 \right) \tag{2.13}$$

Further, it is assumed that Y_t and J_t are independent of each other as well as of $W_t^{\mathbb{Q}\,(1)}$ and $W_t^{\mathbb{Q}\,(2)}$.

Using the independence of Y_t, J_t and the two Wiener processes, one can show that the characteristic function of the SVJ model is [15]:

$$\varphi_T^{SVJ} (u) = \varphi_T^{SV} (u) \cdot \varphi_T^J (u) \tag{2.14}$$

where:

$$\varphi_T^J = \exp\{-\lambda \mu_J iuT + \lambda T((1 + \mu_J)^{iu} \exp(\sigma_J^2 (iu/2)(iu - 1)) - 1)\} \tag{2.15}$$

and $\varphi_T^{SV} (u)$ is defined as in (2.4).

2.3. Multi-factor stochastic volatility model (MFSV)

The multi-factor stochastic volatility model is an extension of the SV model and has been studied by e.g. [5] and [10]. We denote the multi-factor stochastic volatility model MFSV and let the following set of SDEs describe the return process under the risk-neutral measure:

$$\frac{dS_t}{S_t} = (r - \delta)dt + \sqrt{V_t^{(1)}} dW_t^{\mathbb{Q}\,(1)} + \sqrt{V_t^{(2)}} dW_t^{\mathbb{Q}\,(2)} \tag{2.16}$$

$$dV_t^{(1)} = \kappa_1 \left(\theta_1 - V_t^{(1)} \right) dt + \sigma_1 \sqrt{V_t^{(1)}} dW_t^{\mathbb{Q}\,(3)} \tag{2.17}$$

$$dV_t^{(2)} = \kappa_2 \left(\theta_2 - V_t^{(2)} \right) dt + \sigma_2 \sqrt{V_t^{(2)}} dW_t^{\mathbb{Q}\,(4)} \tag{2.18}$$

where the parameters have the same meaning as in (2.1) – (2.3) and the subscripts 1 and 2 indicate to which variance process the parameter is related.

The dependence structure is assumed to be as follows:

$$dW_t^{\mathbb{Q}\,(1)} dW_t^{\mathbb{Q}\,(3)} = \rho_1 dt \tag{2.19}$$

$$dW_t^{\mathbb{Q}\,(2)} dW_t^{\mathbb{Q}\,(4)} = \rho_2 dt \tag{2.20}$$

$$dW_t^{\mathbb{Q}\,(i)} dW_t^{\mathbb{Q}\,(j)} = 0, \quad (i, j) = (1,2), (1,4), (2,3), (3,4) \tag{2.21}$$

In other words, each variance process is correlated with the corresponding Wiener process in the return process, i.e. the diffusion term of which the respective variance process determines the magnitude.

By the independence structure described above, the added diffusion term is independent of the nested SV model return SDE. Since the characteristic function of the sum of two independent variables is the product of their individual characteristic functions, the characteristic function of the MFSV model is determined as:

$$\varphi_T^{MFSV}(u) = \mathbb{E}_0^{\mathbb{Q}}[e^{ius_T}] = S_0^{iu} f\left(V_0^{(1)}, V_0^{(2)}, u, T\right) \tag{2.22}$$

where:

$$f\left(V_0^{(1)}, V_0^{(2)}, u, T\right) = \exp\left\{A(u,T) + B_1(u,T)V_0^{(1)} + B_2(u,T)V_0^{(2)}\right\} \tag{2.23}$$

$$A(u,T) = (r-\delta)iuT + \sum_{j=1}^{2} \sigma_j^{-2}\kappa_j\theta_j\left[(\kappa_j - \rho_j\sigma_j iu - d_j)T - 2\log\left(\frac{1 - g_j e^{-d_j T}}{1 - g_j}\right)\right] \tag{2.24}$$

$$B_j(u,T) = \sigma_j^{-2}(\kappa_j - \rho_j\sigma_j iu - d_j)\left[\frac{1 - e^{-d_j T}}{1 - g_j e^{-d_j T}}\right] \tag{2.25}$$

$$g_j = \frac{\kappa_j - \rho_j\sigma_j iu - d_j}{\kappa_j - \rho_j\sigma_j iu + d_j} \tag{2.26}$$

$$d_j = \sqrt{(\rho_j\sigma_j iu - \kappa_j)^2 + \sigma_j^2(iu + u^2)} \tag{2.27}$$

2.4. Multi-factor stochastic volatility model with jumps (MFSVJ)

The multi-factor stochastic volatility model with jumps that we use in this paper is a variation of the model presented in [5]. However, we use a different approach in the sense that we estimate the model to only one day's data whereas [5] uses a data set spanning over 7 years. We denote the multi-factor stochastic volatility model with jumps MFSVJ, and let the risk-neutral stock price dynamics be described by the following set of SDEs:

$$\frac{dS_t}{S_t} = (r - \delta - \lambda\mu_J)dt + \sqrt{V_t^{(1)}}dW_t^{\mathbb{Q}\,(1)} + \sqrt{V_t^{(2)}}dW_t^{\mathbb{Q}\,(2)} + J_t dY_t \tag{2.28}$$

$$dV_t^{(1)} = \kappa_1\left(\theta_1 - V_t^{(1)}\right)dt + \sigma_1\sqrt{V_t^{(1)}}dW_t^{\mathbb{Q}\,(3)} \tag{2.29}$$

$$dV_t^{(1)} = \kappa_2\left(\theta_2 - V_t^{(2)}\right)dt + \sigma_2\sqrt{V_t^{(2)}}dW_t^{\mathbb{Q}\,(4)} \tag{2.30}$$

where all parameters and variables are defined as in equations (2.1) – (2.3) and (2.10). The distributions of J_t and Y_t are log-normal and Poisson, respectively, according to equations (2.10) and (2.13), and the two variables are independent, both of each other and of the four Wiener processes. The dependence structure between the Wiener processes is the same as in the MFSV model according to equations (2.19) – (2.21).

Due to the independence between the added jump factor and the SDE of the MFSV model, the characteristic function of s_T is obtained in the same way as in the SVJ model, i.e. as the product of the jump-term characteristic function and the characteristic function of the MFSV model:

$$\varphi_T^{MFSVJ}(u) = \varphi_T^{MFSV}(u) \cdot \varphi_T^J(u) \tag{2.31}$$

where $\varphi_T^{MFSV}(u)$ and $\varphi_T^J(u)$ are defined in equations (2.22) and (2.15), respectively.

3. Vanilla option pricing

3.1. Option pricing in the Black-Scholes model

One of the most appealing features of the Black-Scholes model is the existence of an analytical formula for the pricing of European call and put options. Given that the model parameters (essentially σ) are known, the Black-Scholes price of a European call or put option is calculated as:

$$Price_t^{BS} = S_t e^{-\delta(T-t)} N(\omega d_1) - \omega K e^{-r(T-t)} N(\omega d_2) \tag{3.1}$$

where S_t denotes the spot price, K the strike price, r the interest rate, q the dividend yield, $T - t$ the time to maturity and ω is a binary operator equal to 1 for call options and -1 for put options. Further, we have that:

$$d_1 = \frac{\log\left(\frac{S_t}{K}\right) + \left(r - \delta + \frac{\sigma^2}{2}\right)(T - t)}{\sigma\sqrt{T - t}} \tag{3.2}$$

$$d_2 = d_1 - \sigma\sqrt{T - t} \tag{3.3}$$

in which σ is the volatility of the spot price.

3.2. Option pricing in stochastic volatility models

Assuming that the characteristic function of the log-stock price is known analytically, the price of plain vanilla options can be determined using the Fast Fourier Transform (FFT) method first presented in [8]. Using this approach, the call price is expressed in terms of an inverse Fourier transform of the characteristic function of the log-stock price under the assumed stochastic process. The resulting formula can then be re-formulated to enable computation using the FFT algorithm that significantly decreases computation time compared to standard numerical methods such as the discrete Fourier transform.

To derive the call price function in the FFT approach, we follow closely the method of [8], while also allowing for a continuous dividend yield (δ). Denote by s_T and k the natural logarithm of the terminal stock price and the strike price K, respectively. Further, let $C_T(k)$ denote the value of a European call option with pay-off function $f(S_T) = (S_T - K)^+ = (e^{s_T} - e^k)^+$ and maturity at time T. The discounted expected pay-off under $\mathbb{Q}$ is then:

$$C_T(k) = \mathbb{E}_t^{\mathbb{Q}}[e^{-rT}(S_T - K)^+] = \int_k^\infty e^{-rT}(e^{s_T} - e^k)q_T(s_T)ds_T \tag{3.4}$$

where $q_T(s)$ is the risk-neutral density of s_T. As k tends to $-\infty$, (3.4) translates to:

$$\lim_{k\to-\infty} C_T(k) = \int_{-\infty}^\infty e^{-rT} e^{s_T} q_T(s_T)ds_T = e^{-rT}\mathbb{E}_t^{\mathbb{Q}}[S_T] = S_0 \tag{3.5}$$

This is on the one hand reassuring, as the price of a call with a strike price of zero should equal S_0. On the other hand, in order to apply the Fourier transform to $C_T(k)$ it is required that the function is square integrable for all k, i.e. that $\int_{-\infty}^\infty |C_T(k)|^2 ds_T < \infty \ \forall\, k \in \mathbb{R}$. However, by (3.5), as k tends to $-\infty$:

$$\lim_{k\to-\infty} \int_{-\infty}^\infty |C_T(k)|^2 \, ds_T = \int_{-\infty}^\infty |S_0|^2 \, ds_T \to \infty \tag{3.6}$$

showing that $C_T(k)$ is not square integrable. This problem is solved by introducing the modified call price function:

$$c_T(k) = e^{\alpha k} C_T(k) \tag{3.7}$$

for some $\alpha > 0$. The modified call price function, $c_T(k)$, is then expected to be square integrable for all $k \in \mathbb{R}$, provided that α is chosen correctly. The Fourier transform of $c_T(k)$ takes the following form:

$$\mathfrak{F}\{c_T(k)\} = \int_{-\infty}^\infty c_T(k)e^{i\xi k} \, dk = \psi_T(\xi) \tag{3.8}$$

Combining (3.4), (3.7) and (3.8), we obtain:

$$\begin{aligned}
\psi_T(\xi) &= \int_{-\infty}^\infty e^{i\xi k} \int_k^\infty e^{\alpha k} e^{-(r-\delta)T}(e^{s_T} - e^k)q_T(s_T)ds_T \, dk \\
&= \int_{-\infty}^\infty e^{-(r-\delta)T} q_T(s_T) \int_{-\infty}^{s_T} (e^{s_T+\alpha k} - e^{(1+\alpha)k})e^{i\xi k} \, dk ds_T \\
&= \int_{-\infty}^\infty e^{-(r-\delta)T} q_T(s_T) \left[\frac{e^{(\alpha+1+i\xi)s_T}}{\alpha + i\xi} - \frac{e^{(\alpha+1+i\xi)s_T}}{\alpha + 1 + i\xi} \right] ds_T \\
&= \frac{e^{-(r-\delta)T}}{\alpha^2 + \alpha - \xi^2 + i(2\alpha+1)\xi} \int_{-\infty}^\infty e^{(-\alpha i - i + \xi)i s_T} q_T(s_T)ds_T
\end{aligned} \tag{3.9}$$

where $\varphi_T(\cdot)$ denotes the characteristic function of s_T. The call price can then be obtained by Fourier inversion of $\psi_T(\xi)$ and multiplication by $e^{-\alpha k}$:

$$C_T(k) = e^{-\alpha k} \cdot \mathfrak{F}^{-1}\{\psi_T(\xi)\} = \frac{e^{-\alpha k}}{2\pi} \int_{-\infty}^{\infty} e^{-i\xi k} \psi_T(\xi)\, d\xi = \frac{e^{-\alpha k}}{\pi} \int_{0}^{\infty} e^{-i\xi k} \psi_T(\xi) d\xi$$

$$\approx \frac{e^{-\alpha k}}{\pi} \sum_{j=1}^{N} e^{-i\xi_j k} \psi_T(\xi_j)\eta, \qquad j = 1, \dots, N.$$

(3.10)

where $\xi_j = \eta(j-1)$ and η is the step size in the integration grid. Equation (3.10) can be re-written as:

$$C_T(k_u) = \frac{e^{-\alpha k_u}}{\pi} \sum_{j=1}^{N} e^{-i\frac{2\pi}{N}(j-1)(u-1)} e^{ib\xi_j} \psi(\xi_j) \frac{\eta}{3}\left(3 + (-1)^j - \mathbf{1}(j-1)_{\{0\}}\right)$$

(3.11)

where $b = \pi/\eta$; $k_u = -b + (2b/N)(u-1)$, $u = 1, \dots, N+1$; and $\mathbf{1}(x)_{\mathcal{M}}$ is the indicator function equal to 1 if $x \in \mathcal{M}$ and 0 otherwise. The term $1/3 \cdot \left(3 + (-1)^j - \mathbf{1}(j-1)_{\{0\}}\right)$ is obtained using the Simpson rule for numerical integration. Note that evaluating (3.10) will give call prices for a range of strikes (k_u). The grid of strikes will be dependent on the choice of the parameters η and N, and call prices for specific strike prices can be obtained e.g. through interpolation.

Now, the idea of writing the call price on the form (3.11) is that it enables the use of the FFT. The FFT is an algorithm to efficiently evaluate summations on the form:

$$X(k) = \sum_{j=1}^{N} e^{-i\frac{2\pi}{N}(j-1)(k-1)} x(j), \qquad k = 1, \dots, N$$

(3.12)

With $x_j = e^{ib\xi_j}\psi(\xi_j)\frac{\eta}{3}\left(3 + (-1)^j - \mathbf{1}(j-1)_{\{0\}}\right)$, (3.11) is a special case of (3.12) and can thus be evaluated using the FFT.

4. Parameter estimation

In order to use the defined models to price options, we must estimate model parameters under the equivalent martingale measure $\mathbb{Q}$. As all four stochastic volatility models describe incomplete markets, i.e. markets where we have more sources of risk than traded assets, it follows that the equivalent martingale measure is not unique [6]. In order to find parameter estimates under the equivalent martingale measure, we calibrate the models to fit observed market prices as closely as possible in some sense (see Section 4.2 below). As a consequence, the estimated model parameters will be according to the market's choice of $\mathbb{Q}$.

4.1. Data

The data set consists of 144 call options written on the Eurostoxx 50 index on the 7th of October 2003 and is the same data set used in [23]. The options have maturities between one month and five years and strike prices ranging from 1082 to 5440, with the spot price being 2461.44. As in [23], we also assume a constant interest rate of 3 % and a dividend yield of 0 %. The implied volatilities of all options in the data set are shown in Appendix B. Figure 1 shows the implied volatility surface spanned by the options in the data set. The surface has been obtained using the stochastic volatility inspired (SVI) method introduced in [17].

Figure 1

Implied volatility surface of the Eurostoxx 50 index on the 7th of October 2003 obtained using the stochastic volatility inspired (SVI) method described in [17].
4.2. Loss function

As discussed in the previous section, all models are defined under the risk-neutral measure. Hence, parameter estimates are obtained by calibrating the model to fit observed option prices (i.e. by making the model match observed option prices by altering the parameters). More formally, optimal parameter estimates under the risk-neutral measure are obtained by solving an optimization problem on the form:

$$\widehat{\Theta} = \arg\min_{\Theta} \mathfrak{L}\big(\{\hat{C}(\Theta)\}^n, \{C\}^n\big) \tag{4.1}$$

where Θ is the parameter vector. $\{\hat{C}(\Theta)\}^n$ is a set of n option prices obtained from the model, $\{C\}^n$ is the corresponding set of observed option prices in the market and $\mathfrak{L}(\cdot)$ is some loss function that quantifies the model's goodness of fit with respect to observed option prices. In this thesis, we consider four of the most common loss functions found in the literature, namely are the dollar mean squared error (\$ MSE), the log-dollar mean squared error (L\$ MSE) the percentage mean squared error (% MSE) and the implied volatility mean squared error (IV MSE):

$$\$\,MSE(\Theta) = \frac{1}{n}\sum_{i=1}^{n} w_i \left(C_i - \hat{C}_i(\Theta)\right)^2 \tag{4.2}$$

$$L\$\,MSE(\Theta) = \frac{1}{n}\sum_{i=1}^{n} w_i \left(\log(C_i) - \log\left(\hat{C}_i(\Theta)\right)\right)^2 \tag{4.3}$$

$$\%\,MSE(\Theta) = \frac{1}{n}\sum_{i=1}^{n} w_i \left(\frac{C_i - \hat{C}_i(\Theta)}{C_i}\right)^2 \tag{4.4}$$

$$IV\,MSE(\Theta) = \frac{1}{n}\sum_{i=1}^{n} w_i \left(\sigma_i - \hat{\sigma}_i(\Theta)\right)^2 \tag{4.5}$$

where σ_i is the Black-Scholes implied volatility of option i, and $\hat{\sigma}_i(\Theta)$ denotes the corresponding Black-Scholes implied volatility obtained using the model price as input, and w_i is an appropriately chosen weight.

The choice of loss function is important and has many implications. The \$ MSE function minimizes the squared dollar error between model prices and observed prices and will thus favor parameters that correctly price expensive options, i.e. deep in-the-money (ITM) and long-dated options. The log-dollar MSE function mitigates this problem as the logarithm of the prices are more similar in magnitude than the actual prices. The % MSE function adjusts for price level by dividing the error by the market price, making it less biased towards correctly pricing expensive options. On the contrary, the % MSE function will put emphasis on options with prices close to zero, i.e. deep out-of-the-money (OTM) and short-dated options. The IV MSE function instead minimizes implied volatility errors, making options with higher implied volatility carry greater importance in the estimation. Due to the shape of the volatility smirk, this will in general put more weight on options with low strike prices, and less weight on options with high strike prices.

The existing literature has focused on the choice of loss function both for evaluation purposes [10], as well as for computational purposes. The reason for the latter is that most commonly proposed loss functions are non-convex and have several local (and perhaps global) minima, making standard optimization techniques unqualified [13]. Detlefsen & Härdle [14] study four different loss functions for estimation of stochastic volatility models and conclude that the most suitable choice once the models of interest have been specified is an implied volatility error metric, as this best reflects the characteristics of an option pricing model that is relevant for

pricing out-of-sample. They also show that this choice leads to good calibrations in terms of relatively good fits and stable parameters. On a technical note, the IV MSE function is sometimes preferred to the other loss functions because it does not have the same problems with heteroskedasticity that can affect the estimation [10].

It has also been shown, e.g. by [22], that the choice of weighting (w_i) has a large influence on the behavior of the loss function for optimization purposes, and thus must be made with care. Two common methods are to either include the bid-ask spread of the options as a basis for weighting, giving less weight to options of which there is greater uncertainty of the true price (i.e. options wide a wide bid-ask spread) or to choose weights according to the number of options within different maturity categories.

In this thesis, we consider all loss functions (4.2) – (4.5). As the calculation of the Black-Scholes implied volatility has to be carried out numerically, calibration under the IV MSE loss function is very time consuming. To mitigate this problem, we instead consider an approximate IV MSE loss function:

$$IV\,MSE(\Theta) = \frac{1}{n}\sum_{i=1}^{n} w_i\big(\sigma_i - \hat{\sigma}_i(\Theta)\big)^2 \approx \frac{1}{n}\sum_{i=1}^{n} w_i\left(\frac{C_i - \hat{C}_i(\Theta)}{\mathcal{V}_i^{BS}}\right)^2 \tag{4.6}$$

where $\mathcal{V}_i^{BS}$ denotes the Black-Scholes Vega[1] of option i.

The modified IV MSE loss function (4.6), where the pricing error is divided by the Black-Scholes Vega, is obtained by considering the first order approximation:

$$\hat{C}_i(\Theta) \approx C_i + \mathcal{V}_i^{BS} \cdot (\hat{\sigma}_i(\Theta) - \sigma_i) \tag{4.7}$$

Re-arranging the terms yields:

$$\hat{\sigma}_i(\Theta) - \sigma_i \approx \frac{\hat{C}_i(\Theta) - C_i}{\mathcal{V}_i^{BS}} \tag{4.8}$$

Similar methods are used by [2], [9], [11], [24] and [25], among others, and significantly reduce computation time.

For all loss functions, we choose the weighting w_i such that all maturities are given the same weight in the calibration. Within each maturity category, all options are assigned equal weights. Our weighting is thus defined as:

$$w_i = \frac{1}{n_m \cdot n_{k_m}} \tag{4.9}$$

---

[1] Vega is the sensitivity of the option price with respect to volatility in the Black-Scholes model, i.e. $\mathcal{V}_i^{BS} = \partial C_i^{BS}/\partial \sigma_i$.

11

where n_m is the number of maturities and n_{k_m} is the number of options with the same maturity as option i. This choice of weighting is also used in [14].

4.3. Estimation procedure

The estimation was carried out using the `lsqnonlin` function in MATLAB. Since lsqnonlin is a local optimizer, we cannot know if the obtained solutions are the global minimums of the loss function. In order to maximize the chances of obtaining global solutions, each model was estimated ten times with different sets of starting values for the parameters. The starting values were randomly chosen on uniform intervals based on parameter estimates in previous studies such as [3], [11] and [23].

Apart from obvious bounds on the parameters, such as e.g. non-negative speed of mean-reversion and variances, we have implemented the so called Feller [15] condition, namely that $2\kappa\theta < \sigma^2$. The Feller condition ensures that the variance process is strictly positive and cannot reach zero. We implement the Feller condition by introducing the auxiliary variable $\Psi = 2\kappa\theta - \sigma^2$, and optimize using this variable rather than κ itself. The Feller condition then reduces to $\Psi > 0$, and κ can subsequently be calculated as $\kappa = (\Psi + \sigma^2)/2\theta$.

5. Barrier option pricing

5.1. The Black-Scholes model

One of the most appealing features of the Black-Scholes model is that it does not only provide analytical formulas for the pricing of vanilla options, but also for a range of exotic options. The price of a barrier option will depend on the regular Black-Scholes parameters $S_0, K, r, \delta, T, \sigma$ as well as on the barrier level, denoted H.

We obtain the pricing formulas from [26], where also derivations and intuition is provided. As mentioned in Section 1, we consider down-barrier call options with $H < K$ and up-barrier call options with $H > K$. All options considered are struck at the money (ATM), i.e. $K = S_0$.

Denote by $C_{BS}(S, K)$ and $P_{BS}(S, K)$ the Black-Scholes price of plain vanilla call and put options, respectively (the variables r, δ, T and σ are in all instances) and let $v = r - \delta - \frac{\sigma^2}{2}$ and $d_{BS}(S, K) = \frac{\log(S/K) + vT}{\sigma\sqrt{T}}$. Further, we denote by $\Phi(x)$ the standard normal cumulative distribution function.

Using this notation, the prices of the barrier options can be calculated as:

$$UI_{BS} = \left(\frac{H}{S}\right)^{\frac{2v}{\sigma^2}} \left\{ P_{BS}\left(\frac{H^2}{S}, K\right) - P_{BS}\left(\frac{H^2}{S}, H\right) + (H - K)e^{-rT}\Phi(-d_{BS}(H, S)) \right\}$$
$$+ C_{BS}(S, H) + (H - K)e^{-rT}\Phi(d_{BS}(S, H)) \tag{5.1}$$

12

$$UO_{BS} = C_{BS}(S,K) - C_{BS}(S,H) - (H-K)e^{-rT}\Phi\big(d_{BS}(S,H)\big)$$
$$- \left(\frac{H}{S}\right)^{\frac{2\nu}{\sigma^2}}\left\{C_{BS}\left(\frac{H^2}{S},K\right) - C_{BS}\left(\frac{H^2}{S},H\right) - (H-K)e^{-rT}\Phi\big(d_{BS}(H,S)\big)\right\}$$

(5.2)

$$DI_{BS} = \left(\frac{H}{S}\right)^{\frac{2\nu}{\sigma^2}} C_{BS}\left(\frac{H^2}{S},K\right)$$

(5.3)

$$DO_{BS} = C_{BS}(S,K) - \left(\frac{H}{S}\right)^{\frac{2\nu}{\sigma^2}} C_{BS}\left(\frac{H^2}{S},K\right)$$

(5.4)

By definition, we have that $DI_{BS} + DO_{BS} = UI_{BS} + UO_{BS} = C_{BS}$, i.e. that the sum of a knock-in call option and a knock-out call option with the same strike price and barrier will equal the price of a vanilla call option.

To implement the Black-Scholes model, we need to estimate the volatility parameter σ. A common approach to finding the appropriate sigma is to observe the implied volatility surface (see Figure 1 in Section 4) and choose a volatility corresponding to the strike price and maturity in question. As neither the skew nor the term structure are incredibly steep around the ATM level for the considered maturities of one and three years, we have chosen to use the implied volatilities of the options with strike price and maturity closest to 2461.44 (ATM) and $T = 1$ and $T = 3$. This leads to $\sigma_{1y} = 24.46\,\%$ and $\sigma_{3y} = 24.00\,\%$.[2]

5.2. Monte Carlo simulation

In order to price the path-dependant barrier options using the stochastic volatility models, we use Monte Carlo simulation. The first step towards pricing options using Monte Carlo simulation is to re-formulate the continuous processes of the various models to discrete time. For this purpose we use Euler-schemes.

Although we have implemented the Feller condition, there will be a risk that the variance process take negative values due to the discretization of the processes. For that reason, in each time step, we insert $V_t^+ = \max(V_t, 0)$ instead of V_t, i.e. we floor the variance at zero. Other methods include reflecting barriers, i.e. using $|V_t|$ rather than V_t^+. It has however been shown that the former method is less biased [15]. Note that when the variance is zero in a period, the variance process will have deterministic drift equal to $\kappa\theta dt$ in the next period.

For all models we use a time step of $dt = 1/252$, corresponding to one trading day, and 100 000 simulations.

---

[2] The actual strike price of the chosen options is 101.55 % of the spot price and the maturities are 1.19 and 2.19 years, respectively. See Appendix B for the implied volatilities of all options in the data set.

5.2.1. SV model

The Euler-scheme of the SV model takes the form:

$$S_t = S_{t-1} + (r - \delta)dt + \sqrt{V_t^+} \sqrt{dt} \, Z_t^{(1)} \tag{5.5}$$

$$V_t = V_{t-1}^+ + \kappa(\theta - V_{t-1}^+)dt + \sigma\sqrt{V_t^+}\sqrt{dt} \, Z_t^{(2)} \tag{5.6}$$

where $Z_t^{(1)}$ and $Z_t^{(2)}$ are correlated $N(0,1)$ variables with correlation coefficient ρ.

5.2.2. SVJ model

The Euler-scheme of the SV model takes the form:

$$S_t = S_{t-1} + (r - \delta)dt + \sqrt{V_t^+} \sqrt{dt} \, Z_t^{(1)} + J_t X_t S_{t-1} \tag{5.7}$$

$$V_t = V_{t-1}^+ + \kappa(\theta - V_{t-1}^+)dt + \sigma\sqrt{V_t^+}\sqrt{dt} \, Z_t^{(2)} \tag{5.8}$$

where $Z_t^{(1)}$ and $Z_t^{(2)}$ are defined as in equation (5.5). dX_t is a Poisson counter with intensity λ and is simulated as $\Pr(X_t = 1) = \lambda dt$ and $\Pr(X_t = 0) = 1 - \lambda dt$. Recall from equation (2.13) that the jump size J_t is log-normally distributed. Regular standardization yields:

$$\frac{\log(1 + J_t) - \log(1 + \mu_J) + \sigma_J^2/2}{\sigma_J} \sim N(0,1) \tag{5.9}$$

If we let U_t be an $N(0,1)$ variable, we can simulate the jump size through:

$$J_t = \exp\left(\sigma_J U_t + \log(1 + \mu_J) - \frac{\sigma^2}{2}\right) - 1 \tag{5.10}$$

5.2.3. MFSV model

The discretization of the MFSV model is a natural extension of equations (5.5)–(5.6):

$$S_t = S_{t-1} + (r - \delta)dt + \sqrt{V_t^{(1)+}} \sqrt{dt} \, Z_t^{(1)} + \sqrt{V_t^{(2)+}} \sqrt{dt} \, Z_t^{(2)} \tag{5.11}$$

$$V_t^{(1)+} = V_{t-1}^{(1)+} + \kappa\left(\theta - V_{t-1}^{(1)+}\right)dt + \sigma\sqrt{V_t^{(1)+}}\sqrt{dt} \, Z_t^{(3)} \tag{5.12}$$

$$V_t^{(2)+} = V_{t-1}^{(2)+} + \kappa\left(\theta - V_{t-1}^{(2)+}\right)dt + \sigma\sqrt{V_t^{(2)+}}\sqrt{dt} \, Z_t^{(4)} \tag{5.13}$$

where $Z_t^{(1)}$ and $Z_t^{(3)}$ are correlated $N(0,1)$ variables with correlation ρ_1 and $Z_t^{(2)}$ and $Z_t^{(4)}$ are correlated $N(0,1)$ variables with correlation ρ_2.

5.2.4. MFSVJ model

The discrete form of the MFSVJ model is simply obtained by adding the jump factor from equation (5.7) to equation (5.11):

$$S_t = S_{t-1} + (r - \delta)dt + \sqrt{V_t^{(1)+}}\sqrt{dt}\, Z_t^{(1)} + \sqrt{V_t^{(2)+}}\sqrt{dt}\, Z_t^{(2)} + J_t X_t S_{t-1} \tag{5.14}$$

$$V_t^{(1)+} = V_{t-1}^{(1)+} + \kappa\left(\theta - V_{t-1}^{(1)+}\right)dt + \sigma\sqrt{V_t^{(1)+}}\sqrt{dt}\, Z_t^{(3)} \tag{5.15}$$

$$V_t^{(2)+} = V_{t-1}^{(2)+} + \kappa\left(\theta - V_{t-1}^{(2)+}\right)dt + \sigma\sqrt{V_t^{(2)+}}\sqrt{dt}\, Z_t^{(4)} \tag{5.16}$$

where all variables are defined as in equations (5.10) – (5.13).

6. Results

6.1. Parameter estimates and in-sample fit

Table 1 summarizes the results of the parameter estimation and also display the root mean squared dollar error ($ RMSE) for the four models. Parameter estimates obtained using the IV RMSE, % MSE and Log $ MSE loss functions are shown in Tables A.1 – A.3 in Appendix A.

Table 1

Parameter estimates obtained by minimizing the squared dollar error to a sample of 144 call options on the Eurostoxx 50 index on the 7th of October 2003.

	κ	θ	σ	ρ	λ	μ_J	σ_J	V_0	$\$\,RMSE$
SV	0.5249	0.0705	0.2720	-0.7360				0.0649	2.4956
SVJ	0.5365	0.0630	0.2601	-0.9959	0.4978	0.1258	0.0534	0.0576	1.9178
MFSV	0.7057	0.0673	0.3082	-1.0000				0.0505	1.6832
	0.5545	0.0033	0.0602	0.8981				0.0154	
MFSVJ	0.6779	0.0670	0.3014	-0.9999	0.0706	0.0346	0.0536	0.0509	1.6808
	0.6068	0.0039	0.0690	0.8123				0.0150	

Unsurprisingly, the more advanced multi-factor model produces lower RMSEs than the single-factor models. Common for all models is a strong negative correlation between the return process and the variance process, which adds the empirically observed skew to the return distribution. Notable is however that for both multi-factor models, the second stochastic volatility factor, in both cases with significantly smaller magnitude than the first factor, is positively correlated with the return process.

The estimated parameters are similar across all loss functions. The most notable difference is that the IV MSE loss function result in higher estimates of the speed of mean-reversion (κ) and the

volatility of the variance (σ) than the other loss functions. This however has rather small effect on the in-sample fit, regardless of loss function. The reason for this is that the parameters κ and σ have opposite effects on the behavior of the spot price process. A high value of κ will decrease volatility risk, as the volatility will be more quickly mean-reverting, making volatility shocks less persistent. On the contrary, a high value of σ will increase the magnitude of volatility shocks, increasing volatility risk. The trade-off is visualized in Figure 2 showing an error surface for different choices of κ and σ. We can see that the shape of the error surface more resembles a valley than a bowl, i.e. that the many combinations of κ and σ along the bottom of the valley yield errors of similar magnitude.

Figure 2
Error surface of the SV model for different choices of κ and σ.
As concluded in [23], the in-sample fit of the models is almost perfect. Figure A.1 in Appendix A shows the in-sample fits of the four stochastic volatility models. The figure shows the in-sample fit under the \$ MSE loss function, but the corresponding plots for the other loss functions are almost identical.

6.2. Barrier option prices

Tables A.4 – A.11 in Appendix A show the obtained barrier option prices for the five models and the four loss functions used for estimation. We also show the probabilities that the studied barriers are breached for each model under each loss function in Tables A.12 – A.15.

16

The prices of the four stochastic volatility models are of similar magnitude in most instances. However, for down-and-in options with very low barriers and up-and-out options with barriers close to S_0, we observe large relative price differences simply because the prices are very close to zero making relative price differences very sensitive.

We do not observe any large differences in the prices between loss functions, pointing towards the conclusion that the choice of loss function is not essential for the purpose of barrier option pricing. It should however be noted that that may be a consequence of the data set at hand, in which all loss functions yield very similar parameter estimates. Rather than to neglect the importance of the choice of loss function, these results should be seen as a motivation to conducting larger scale studies on more extensive data sets to examine the importance of the choice of loss function for the purpose of exotic option pricing.

As for the Black-Scholes model, we observe large price differences in comparison to the stochastic volatility models. First, we note that the Black-Scholes price of down-and-in options is significantly lower than the corresponding prices of the stochastic volatility models for barriers below 85 % of the spot price. This observation is rather expected, as one of the main purposes of introducing stochastic volatility models is to model the empirical fact that volatility tends to increase in declining markets. Hence, the stochastic volatility models will introduce a higher probability of the stock price breaching the barrier far below the spot price. In other words, the probability distribution of the stock price at any future time point will be right skewed as compared to the normal distribution, implying higher probabilities of large declines in the stock price that are necessary for down-and-in options with low barriers to end up in the money. This is confirmed by the probabilities shown in Tables A.12 – A.15 in Appendix A. The probabilities of the spot price breaching the lower barriers is significantly higher in the stochastic volatility models for barriers of 80 % of the spot price and below, regardless of loss function used for parameter estimation. Given that there are rather small price differences between the vanilla call prices of the models, the relation $DO + DI = call\ option$ states that if there is a difference in price between down-and-in options, there must be a corresponding reverse price difference in the down-and-out options. However, as the prices of the down-and-out options for very low barriers obviously are much higher than the corresponding down-and-in options, the relative price difference is much smaller. Hence, the relative price differences of several hundred percent for down-and-in options only correspond to relative price differences of a few percent for the down-and-out options.

Second, we note that the Black-Scholes prices of up-and-in barrier options are significantly higher than the corresponding prices of the stochastic volatility models for high barriers, e.g. barriers above 25 % of the spot price. The pattern is most evident for the short maturity options (short in this case meaning a maturity of one year), whereas the difference for the 3-year options becomes evident at even higher levels of the barrier. The probabilities in Tables A.12 – A.15 in Appendix a reveal that this stems from an increased probability that the upper barrier is breached in the Black-Scholes model as compared to the stochastic volatility models. As we have not

derived the actual distributions of the stock price under the stochastic volatility models, this pattern is more difficult to explain. A plausible explanation to the findings is however that the skewness of the distributions of the stock price under the stochastic volatility models decrease the amount of probability mass in the right tail of the distribution, making extreme events on the upside less likely than in the normal distribution assumed in the Black-Scholes model. Although the stochastic volatility models also add kurtosis to the stock price distribution, resulting in distributions with fatter tails than the normal distribution, it seems that in this case the effect of the skewness is more prominent. The pattern is confirmed when looking at the prices of the up-and-out barrier options. As expected given the recently discussed observations, the prices of the up-and-out options are lower in the Black-Scholes model than in the stochastic volatility models, with relative price differences being the largest for barriers close to the spot price.

7.   Conclusion

This thesis examines the performance of the Black-Scholes model and four stochastic volatility models with respect to the pricing of barrier options. Our results show that the choice of loss function for estimation of the model parameters of the stochastic volatility models have little effect on the resulting prices of both vanilla options and barrier options. This result motivates further studies of the impact of the loss function on exotic option prices and parameter estimation.

Further, our results show that the Black-Scholes model yields barrier option prices that differ significantly from the corresponding prices obtained from the stochastic volatility models, although vanilla call prices are very similar. The reason for this is that the stochastic volatility models give rise to a skewed distribution of future spot prices, resulting in higher probabilities of breaching low barriers and lower probabilities of breaching high barriers as compared to the symmetrical normal distribution underlying the Black-Scholes model. For barrier levels close to the spot price, however, the prices are in many cases of similar magnitude.

As for the relationship between the stochastic volatility models, we find that all four models yield similar prices both with respect to vanilla call options and the path-dependent barrier options. This confirms the notion of [23], where it is concluded that large differences in exotic option prices are observed between different classes of models rather than between different models within the same category.
